ABSTRACT

Objective Non-alcoholic fatty liver disease (NAFLD) is the most common cause of abnormal results of liver function tests. Earlier research showed that polyenylphosphatidylcholine (PPC) has hepatoprotective effects and thus can be used for the treatment of NAFLD and the prevention of its progression. Accordingly, the aim of this observational study was to evaluate if PPC administered as adjunctive therapy in routine clinical practice can effectively improve liver function tests of NAFLD in Russian patients with associated metabolic comorbidities.

Design A total of 2843 adult patients with newly diagnosed NAFLD, who had a least one of four comorbidities, namely, overweight/obesity, hypertension, type 2 diabetes mellitus, and hypercholesterolaemia, and who were prescribed 1.8 g/day of PPC as an adjunctive treatment to standard care, were enrolled during 2015–2016. Laboratory data were collected at baseline and 12 and 24 weeks of the study, and included liver function tests (aspartate aminotransferase (AST), alanine aminotransferase (ALT), gamma-glutamyl transferase (GGT)), fasting plasma glucose, and lipid profile.

Results Overall, 2263 patients (79.6%) had at least two metabolic comorbidities associated with NAFLD, and overweight/obesity was the most common comorbidity reported in 2298 (80.8%) patients. At 24 weeks, there was a significant decrease in liver enzyme levels (all $p < 0.001$ compared with baseline). Across the four comorbidity subgroups, there was a mean drop of ALT levels ranging from 19.7 to 22.0 U/L, AST from 16.9 to 18.4 U/L, and GGT from 17.2 to 18.7 U/L. Similar findings were reported in subgroups with either one, two, three, or four comorbidities, with a significant decrease in liver enzyme levels ranging from 18.4 to 22.4 U/L for ALT, 14.8 to 18.7 U/L for AST, and 15.5 to 19.5 U/L for GGT.

Conclusions Adjuvant treatment with PPC resulted in consistent improvements in liver enzymes in patients with newly diagnosed NAFLD and associated metabolic comorbidities.

Trial registration number NCT00063622.

Summary box

What is already known about this subject?

- ▶ Non-alcoholic fatty liver disease (NAFLD) is currently the most common cause of abnormal results of liver function tests.
- ▶ Aspartate aminotransferase (AST), alanine aminotransferase (ALT), and gamma-glutamyl transferase (GGT), which are markers of liver injury, are still considered as useful surrogate measures of NAFLD for clinical practitioners; recently, however, their diagnostic value has been challenged.
- ▶ Previous research has indicated that polyenylphosphatidylcholine (PPC) might have a positive influence on liver enzyme levels, as well as on serum lipid profile.

What are the new findings?

- ▶ PPC administered as adjunctive therapy in patients with NAFLD with metabolic comorbidities consistently lowered AST, ALT and GGT levels, irrespective of the nature and number of associated comorbidities.
- ▶ Although a low rate of achieving total cholesterol levels below 5.0 mmol/L was noted at the end of the study in the overall patient population, significant improvements in lipid parameters were observed in both patients receiving PPC only and in those receiving PPC in addition to statins and/or fibrates.

Summary box

How might it impact on clinical practice in the foreseeable future?

- ▶ PPC has a promising role in the management of both NAFLD and its extrahepatic manifestations, including abnormal liver enzyme and lipid levels.
- ▶ Liver enzymes can be useful markers for monitoring the progression of NAFLD over time. There is a need for further investigation on the association of liver enzymes with NAFLD, which might help improve the diagnosis, management and risk prediction of NAFLD progression and provide a more accurate indicator for chronic metabolic liver injury.
- ▶ Individualised intervention strategies should be adopted in Russia to improve the management of patients with NAFLD with associated dyslipidaemia.

finally cirrhosis.^{2 3} NAFLD is recognised as the hepatic manifestation of the metabolic syndrome, which includes obesity, dyslipidaemia, hypertension and type 2 diabetes mellitus (T2DM).^{3–5} Obesity, in particular, is often associated with NAFLD, as the degree of steatosis was found to be correlated with body mass index (BMI).^{6 7}

The World Gastroenterology Organisation recommends a hierarchical resource-sensitive approach to the diagnosis of NAFLD.⁸ Even though liver biopsy remains the gold standard, it is impractical as a diagnostic tool because it is invasive and expensive.⁹ Thus, non-invasive and more affordable tools, based on a biological approach (such as serum biomarkers and liver enzymes), have been proposed for the diagnosis and staging of NAFLD.^{8 9} Indeed, aspartate aminotransferase (AST), alanine aminotransferase (ALT), and gamma-glutamyl transferase (GGT) have been shown to be useful surrogate measures of NAFLD.^{8 10}

As a result of increasing rates of obesity worldwide, NAFLD is currently the most common cause of abnormal results of liver function tests.^{11–13} The usual observed biochemical pattern in hepatic steatosis due to NAFLD is of increased levels of transaminases, with ALT levels exceeding those of AST.¹⁴ However, with the progression of hepatic steatosis to NASH and associated hepatic fibrosis, AST levels increase with a resultant rise in the AST to ALT ratio.^{14–16} GGT levels may also be modestly increased.¹⁴ At the same time, however, it has been shown that liver enzyme levels do not correlate with the histological severity of NAFLD.¹⁷ Of note, up to 80% of patients with NAFLD have no liver enzyme abnormalities, implying that normal transaminase levels do not exclude steatosis.^{18 19} Nevertheless, ALT, AST, the AST/ALT ratio and GGT are included in different multibio-marker panels aimed to optimise the diagnostic accuracy of NAFLD.²⁰ The AST to ALT ratio, in particular, can provide important diagnostic clues. The normal AST to ALT ratio is approximately 0.8, and it is usually <1.0 in NAFLD, although it may be >1.0 with the development of cirrhosis.^{21 22}

There is a wide variety of pharmaceutical agents currently in use or in clinical development for NAFLD and NASH. However, there are insufficient data supporting their beneficial effects on liver enzyme levels. For example, ursodeoxycholic acid, metformin, and vitamin E failed to have a significant influence on liver histology and on liver function tests in several large placebo-controlled trials.^{23–25} In contrast, pioglitazone led to significant improvements in hepatic steatosis, inflammation, insulin resistance, and liver enzyme levels in the phase III, placebo-controlled Pioglitazone Versus Vitamin E Versus Placebo for the Treatment of Non-diabetic Patients with Non-alcoholic Steatohepatitis (PIVENS) trial.²⁶ However, pioglitazone use is associated with several safety concerns, including postmenopausal bone loss and increased risk of bladder cancer.²⁷ Similarly, although vitamin E was found to be superior to placebo in the PIVENS trial,²⁶ studies have shown that vitamin E supplementation significantly increases the risk of haemorrhagic stroke and prostate cancer.^{28 29} Among emerging pharmacological options, both obeticholic acid and selonsertib failed to achieve the primary endpoint of NASH resolution and of fibrosis improvement in the phase III Randomized Global Phase 3 Study to Evaluate the Impact on NASH With Fibrosis of Obeticholic Acid Treatment (REGENERATE) and Safety and Efficacy of Selonsertib in Adults With Compensated Cirrhosis Due to Nonalcoholic Steatohepatitis (STELLAR)-4 trials, respectively.^{30 31} Hence, despite considerable research and multiple clinical trials, the management of NAFLD and of NASH is not satisfactory at the present time.³² Thus, any therapeutic intervention, which can target fat accumulation in the liver and improve liver enzyme levels, would be of great value.^{33 34} Essential phospholipids (EPLs) are highly purified phosphatidylcholine fractions extracted from the semen of soybeans, containing linoleic acid and other unsaturated fatty acids.^{33–35} Polyenylphosphatidylcholine (PPC) is the main active ingredient in EPL.³⁵ Earlier research on animal studies showed that PPC has protective effects against lipid peroxidation, oxidative stress and hepatic fibrosis, and thus can be used for the treatment of NAFLD and the prevention of its further progression.^{36–38}

In Russia, the estimated prevalence of NAFLD in the adult population is 37%.³⁹ Considering that EPL was indicated as antioxidant therapy for NAFLD in the Russian Guidelines for the Diagnosis and Management of NAFLD⁴⁰ and having several clinical trials in which PPC had a positive influence on liver enzyme levels,^{5 41 42} the purpose of this real-life observational study was to evaluate if PPC administered as adjunctive therapy can effectively improve liver function tests of newly diagnosed NAFLD in Russian patients with associated metabolic comorbidities.

METHODS**Patients**

A detailed description of the study methodology has already been published elsewhere.⁴³ Briefly, patients aged 18–60 years, with newly diagnosed NAFLD and who had already been receiving PPC (Essentiale Forte N, which

contains 300 mg of EPL) prescribed by a physician as an adjunctive treatment to standard care (within 30 days before enrolment), were prospectively and consecutively enrolled at 174 medical sites between 2015 and 2016, and were afterwards prospectively observed. NAFLD diagnosis was based on clinical examination, laboratory tests, and ultrasonography. In addition, eligible patients had at least one of the following concomitant diseases: (1) hypertension diagnosed by a cardiologist, (2) T2DM diagnosed by an endocrinologist, (3) high-serum cholesterol (defined as a total cholesterol (TC) level of ≥ 5.0 mmol/L), and/or (4) overweight/obesity ($\text{BMI} \geq 27 \text{ kg/m}^2$). Major exclusion criteria were the presence of other severe acute or chronic conditions (including other liver diseases and cancers) and treatment with other hepatoprotective drugs within 30 days prior to study enrolment. All study participants gave signed informed consent prior to study inclusion.

Data collection

Individual patient data were collected at three time-points: baseline and 12 and 24 weeks. All patients had a complete history and physical examination performed at baseline. The history of prescription drug use and the prescribed dosage and duration of PPC therapy were assessed by the examining physicians.

Laboratory data collected from all patients at each study visit included liver function tests (AST, ALT, GGT, total bilirubin, alkaline phosphatase (ALP), albumin, prothrombin time, gamma-globulin, and serum iron); fasting plasma glucose (FPG); and lipid profile (TC, low-density lipoprotein (LDL) cholesterol, very-low-density lipoprotein (VLDL) cholesterol, high-density lipoprotein (HDL) cholesterol, and triglyceride (TG)). Furthermore, at baseline, additional test results, including hepatitis B serology, hepatitis C antibodies, serum creatinine, ferritin, blood urea nitrogen, immunoreactive insulin, and urine microalbumin, were analysed. In the study analysis, prothrombin time results were reported as percentage activity (also known as prothrombin activity).

The reference intervals of liver function tests used in this study were based on patient data from different laboratories across Russia, and included ALT, up to 41 U/L for men and 33 U/L for women; AST, up to 50 U/L for men and 35 U/L for women; GGT, up to 49 U/L for men and 32 U/L for women; ALP, 40–150 U/L; total bilirubin, 3–17 $\mu\text{mol/L}$; and albumin, 35–50 g/L.

Study endpoints

This study aimed to evaluate the effectiveness of PPC adjunctive therapy in improving liver function tests in the overall study population throughout the 24-week study period, and also according to the nature and number of metabolic comorbidities associated with NAFLD.

Since previous randomised controlled trials have reported that EPL intake was associated with an improved lipid profile,^{44 45} a post hoc analysis was performed to evaluate changes in lipid profile (ie, TC, LDL cholesterol,

HDL cholesterol, VLDL cholesterol, and TG) from baseline to both weeks 12 and 24 of the study in two subgroups: patients receiving PPC only, and those receiving PPC in addition to lipid-lowering agents (mainly the most used in routine clinical practice in Russia, ie, statins and/or fibrates).

Statistical analysis

The population set used for statistical analysis comprised all eligible enrolled patients who provided adequate laboratory data. Continuous variables were represented as mean, SD, median, and IQR. Categorical variables were reported as numbers and percentages. At weeks 12 and 24 of the study, mean \pm SD changes in laboratory parameters from baseline were calculated.

To compare the means of normally distributed variables, Student's t-test was performed. Non-parametric tests, such as the Wilcoxon-Mann-Whitney test, were used to compare continuous non-normally distributed variables. The χ^2 test and Fisher's exact test were used for comparison of frequency data. As multiple comparisons were performed in the post hoc analysis, p values were adjusted using the Benjamini-Hochberg procedure.⁴⁶

All statistical tests were two-sided and were performed at a 0.05 significance level. Statistical analyses were conducted using SAS V.9.3.

RESULTS

Patient characteristics

A total of 2843 patients with newly diagnosed NAFLD were included, of which 2827 (99.4%) completed the study. Demographic and baseline characteristics of the study population are summarised in [table 1](#). The mean \pm SD age of the female study participants was significantly higher than that of their male counterparts (49.7 ± 8.2 vs 47.2 ± 9.0 years, $p < 0.001$). The great majority (2434/2843, 85.6%) of patients were non-smokers, and only 201 (7.1%) consumed alcohol at least once a week.

Overweight/obesity was the most common comorbid condition in the study population (80.8%). The majority of patients (2263/2843, 79.6%) had at least two metabolic comorbidities ([table 1](#)). At baseline, statins were the most frequently prescribed medications in patients with overweight/obesity (601/2298, 26.2%) and in those with hypercholesterolaemia (698/2122, 32.9%). Among hypertensive patients, ACE inhibitors were the most commonly prescribed medications (588/1642, 35.8%). Biguanides (specifically metformin) were prescribed to 241/477 (50.5%) patients with T2DM. Overall, 1092/2843 (38.4%) patients did not receive any comorbidity-related medications.

Staging of NAFLD showed that simple steatosis was the most frequently seen clinical form of NAFLD, diagnosed in 2128 patients (74.9%). NASH was detected in 712 patients (25.0%), and only three patients (0.1%) suffered from fibrosis. Cirrhosis was not detected in any of the patients.

Table 1 Demographic and baseline characteristics of the study population (n=2843)

Baseline characteristic	Study population (n=2843)

*Patients may have more than one comorbid condition.

BMI, body mass index; T2DM, type 2 diabetes mellitus.

Almost all study participants (2837/2843, 99.8%) were prescribed by their physicians 1.8g of PPC administered in three divided doses per day.

Laboratory findings in the overall study population

The baseline biochemical parameters of the study population are presented in [table 2](#). As expected, mean transaminases levels at baseline were above the upper limit of normal. The mean serum levels of GGT and total bilirubin at baseline were also moderately increased. However, other liver function parameters, including albumin, ALP, and prothrombin activity were within the normal reference ranges defined in our study. Results of the baseline lipid and glycaemic profiles revealed that the study population had on average high TC and TG levels, impaired FPG, and increased haemoglobin A1c levels ([table 2](#)). Overall, 36.2%, 52.3%, and 39.8% of patients had normal serum levels of ALT, AST, and GGT, respectively, at baseline ([table 3](#)).

There was a consistent and significant reduction of serum ALT, AST, and GGT levels throughout the 24-week study period ([figure 1](#)). Compared with baseline, mean ALT levels decreased by 20.0 U/L, mean AST by 16.5 U/L, and mean GGT by 15.9 U/L at 24 weeks of the study. These changes were already statistically significant at 12 weeks (all $p<0.001$ by paired t-test for both timepoints). At the end of the study, ALT, AST, and GGT levels were normal in 75.8%, 89.2%, and 62.5% of patients, respectively (all $p<0.001$ compared with baseline). Serum liver enzyme levels were higher than twice the upper limit of normal in up to 3.6% of patients ([table 3](#)).

Laboratory findings by nature and number of comorbidities

At baseline, high levels of liver enzymes, namely, ALT, AST and GGT, were reported in all four comorbidity subgroups: hypertension, overweight/obesity, T2DM, and hypercholesterolaemia. Baseline liver enzyme levels were similar across comorbidity subgroups, with the highest mean ALT, AST, and GGT values recorded in patients with NAFLD with T2DM ([table 4](#)). At 24 weeks of the study, there was a significant decrease in liver enzyme levels in all four comorbidity subgroups (all $p<0.001$ compared with baseline), with a mean drop of ALT levels ranging from 19.7 to 22.0 U/L, of AST from 16.9 to 18.4 U/L, and of GGT from 17.2 to 18.7 U/L ([table 4](#)).

In the subgroups of patients with either one, two, three, or four comorbidities, elevated baseline levels of ALT, AST and GGT were also noted ([table 4](#)). Moreover, it appears that the increasing number of metabolic comorbidities at baseline was associated with higher liver enzyme levels ([table 4](#)). At 24 weeks of the study, there was a significant decrease in liver enzyme levels ($p<0.001$ compared with baseline) in the subgroups with either one, two, three, or four comorbidities, ranging from 18.4 to 22.4 U/L for ALT, from 14.8 to 18.7 U/L for AST, and from 15.5 to 19.5 U/L for GGT.

Post hoc analysis results: changes in serum lipid profile

Of the 2843 enrolled patients, 2077 (73.1%) were not undergoing any form of lipid-lowering therapy, and 766 (26.9%) reported the use of statins (in 764 patients) or fenofibrate (in 2 patients). At baseline, patients treated with lipid-lowering therapy (compared with

in both subgroups (all $p < 0.05$). On post hoc comparison of the mean differences in lipid profiles between the two subgroups (figure 2), patients undergoing lipid-lowering therapy had significantly greater improvements in all lipid parameters at both 12 and 24 weeks (all $p < 0.05$).

Among patients who underwent any form of lipid-lowering therapy in addition to PPC, 96.6% had higher than normal TC levels at baseline vs 62.7% at the end of the study. Similarly, among those who did not undergo lipid-lowering therapy, 79.6% and 59.7% had elevated TC levels at baseline and at study end, respectively. The proportions of patients with normal TC levels at 24

weeks of the study were comparable in both subgroups (table 5).

DISCUSSION

This study showed that adjuvant treatment with EPL resulted in consistent improvements in liver enzymes compared with baseline in patients with newly diagnosed NAFLD and metabolic comorbidities. Although the beneficial effect of PPC adjunctive therapy might have been enhanced by the use of concomitant oral antidiabetic, antihypertensive, and/or lipid-lowering agents for the treatment of the associated metabolic comorbidities, the improvement of liver function tests seems to be genuinely induced by EPL regardless of the types of concomitant medications prescribed. Patients in our study had already been receiving medications for their comorbidities at least 6 months prior to their enrolment, yet at baseline, most of them presented with abnormal liver enzyme levels. In addition, liver enzyme levels were significantly reduced after PPC therapy in both patients receiving comorbidity-related medications ($n=1751$) and in those not receiving any comorbidity-related medications ($n=1092$).

In our study population, mildly raised transaminases (with ALT>AST) and GGT were detected at baseline. This is in line with previous studies describing the biochemical alterations of NAFLD in patients with associated metabolic comorbidities.^{10 47} For instance, in a cross-sectional study from Eastern India evaluating the profile of liver enzymes in 310 patients with impaired glucose tolerance and newly diagnosed untreated T2DM, subjects with NAFLD had significantly higher ALT, AST, GGT and AST/ALT ratio compared with subjects without NAFLD ($p \leq 0.02$ by unpaired t-test).¹⁰ However, no significant

HDL, high-density lipoprotein; LDL, low-density lipoprotein; LPT, undergoing lipid-lowering therapy; NLPT, not undergoing lipid-lowering therapy; TG, triglyceride; VLDL, very-low-density lipoprotein.

difference in ALP levels was detected between patients with NAFLD and subjects without NAFLD ($p = 0.09$).¹⁰ Similarly, in our study, ALP levels were within the normal reference range. Angulo and colleagues have reported that an AST to ALT ratio of > 1.0 significantly correlated ($p = 0.03$) with the presence of advanced liver fibrosis in 144 patients with well-defined NASH.¹⁵ Thus, the AST to ALT ratio can be of help in detecting progression to more advanced liver disease in patients with NAFLD who initially present with no or trivial fibrosis.¹⁵ In our study, most patients presented with an AST to ALT ratio of < 1.0 . That is expected, since liver fibrosis was reported in only 3/2843 patients (0.1%).

The pathogenesis of liver damage in NAFLD is not thoroughly understood. Hepatic insulin resistance can play an important role in liver dysfunction, and inflammatory cytokines, including tumour necrosis factor and interleukin-6, have also been proposed in the pathogenesis of hepatocellular injury, leading to mild to moderate increase of liver enzymes.^{47 48} Thus, ALT, AST and GGT are markers of liver injury.¹⁰ In a prospective study of 5237 healthy Korean men, serum ALT concentrations were found to be more closely associated with the development and progression of NAFLD than either AST or GGT concentrations.⁴⁹ This finding could be partially explained by the higher specificity of ALT for liver

Table 5 Proportion of patients with controlled (<5.0) and uncontrolled (≥5.0) levels of TC (mmol/L) throughout the study in both subgroups: post hoc analysis

Lipid-lowering drug treatment (n=766)	Baseline	12 weeks	24 weeks
TC<5.0 mmol/L	23 (3.0)	86 (11.2)	279 (36.4)
TC≥5.0 mmol/L	740 (96.6)	660 (86.2)	480 (62.7)
Unavailable data	3 (0.4)	20 (2.6)	7 (0.9)
No lipid-lowering drug treatment (n=2077)	Baseline	12 weeks	24 weeks
TC<5.0 mmol/L	370 (17.8)	482 (23.2)	691 (33.3)
TC≥5.0 mmol/L	1653 (79.6)	1387 (66.8)	1240 (59.7)
Unavailable data	54 (2.6)	208 (10.0)	146 (7.0)

Data are expressed as n (%). Percentages are calculated as n/N.
TC, total cholesterol.

injury, as well as by the contribution of ALT as a glucogenic enzyme.^{49 50} It has also been suggested that ALT might be a preclinical marker of NAFLD, since slightly increased serum ALT levels might reflect subclinical (or ultrasonography-undetectable) early fatty changes in the liver (hepatic steatosis), which predate the overtly detectable NAFLD.⁴⁹

Although the exact mechanism through which EPLs exert their beneficial hepatoprotectant effect is still unknown,⁵¹ EPL administration has been shown to increase the percentage of PPC in the membranes of hepatocytes, blood corpuscles and pancreatic tissue, among other tissues.⁵² Due to the intriguing ability of PPC to incorporate into damaged sections of hepatic cell membranes,⁵³ increasing the amount of PPC in membranes results in increased membrane fluidity and maintains membrane-dependent functions.^{52 53} PPC administration has also been found to ameliorate an ethanol-induced decrease in phosphatidylethanolamine N-methyltransferase activity and to correct phospholipid and phosphatidylcholine depletions.⁵⁴ This could be one of the mechanisms through which PPC exerts its antifibrotic effect.⁵³

The hepatoprotective effect of EPL has been widely investigated in several animal studies.^{55–61} In alcohol-fed baboons with fatty livers, long-term administration of PPC prevented the development of septal fibrosis.^{55 56} Moreover, PPC stimulated collagenase activity in cultured hepatic stellate cells,⁵⁶ an effect that may contribute to the prevention of fibrosis by promoting the breakdown of collagen in alcoholic as well as in non-alcoholic forms of liver injury.^{56 57} In a 2009 study conducted in ethanol-fed peroxisome proliferator-activated receptor alpha-null mice, PPC markedly ameliorated ethanol-induced hepatocyte damage and hepatitis.⁵⁸ These effects were likely a consequence of decreased oxidative stress, as shown by a significant improvement in serum AST and ALT levels ($p<0.01$ for both enzymes) and the histology of hepatitis ($p<0.01$), and by the downregulation of reactive oxygen species-generating enzymes.⁵⁸ More recently, Chen and colleagues⁶¹ demonstrated an improved liver function in rats with liver injury treated orally with

phosphatidylcholine. These phosphatidylcholine-treated rats also exhibited a significantly lower portal pressure compared with untreated rats with liver injury. Additionally, liver histopathological changes were improved after phosphatidylcholine therapy, as collagen fibres gradually decreased and damaged hepatic lobules were partly repaired.⁶¹

In the present study, there was a mean drop of ALT levels ranging from 19.7 to 22.0 U/L, of AST from 16.9 to 18.4 U/L, and of GGT from 17.2 to 18.7 U/L across the four comorbidity subgroups. This is line with the findings of previous clinical studies evaluating PPC in patients with NAFLD with metabolic comorbidities.^{5 33 35} In one study conducted in 28 patients with NAFLD with T2DM who received 2.1 g/day of PPC as an adjuvant treatment, a significant reduction in liver function tests was observed after EPL treatment.³³ ALT, AST and GGT levels, respectively, decreased by a mean of 17.4, 10.4 and 9.1 U/L after 6 months of treatment with PPC adjunctive therapy, and this decrease was observed from the beginning of PPC therapy ($p<0.05$ compared with baseline for all three liver enzymes at months 2, 4, and 6 of treatment).³³ Similarly, in a non-randomised, open-label trial by Padma and colleagues in 293 patients with NAFLD treated with EPL administered three times per day daily for 90 days, there was a decrease in liver enzyme levels, which was significant at days 60 and 90 of the study ($p<0.05$ compared with baseline for both timepoints).³⁵ More recently, Dajani *et al* conducted a prospective, multicentre, open-label study evaluating EPL administered as an adjunctive treatment at 1.8 g/day for 24 weeks, followed by 0.9 g for 48 weeks in a cohort of 324 patients with either lone NAFLD ($n=113$), NAFLD with T2DM ($n=107$), or NAFLD with hyperlipidaemia ($n=104$).⁵ EPL led to notable symptomatic improvement and a mean reduction of ALT of 50.8 U/L and AST of 46.1 U/L per patient ($p<0.01$ compared with baseline for both liver enzymes); liver transaminases levels were reduced after the first 6 months of EPL treatment in 80.5% of patients with lone NAFLD, 84.1% of patients with NAFLD with T2DM, and 87.5% of patients with NAFLD with hyperlipidaemia.⁵ In a double-blind trial also from Russia conducted in 215

diabetic patients with NASH who were randomly allocated to either metformin taken at 1000 mg per day or metformin+1368 mg of PPC per day, a mean reduction of ALT of 21.3 U/L ($p=0.02$), of AST of 12.5 U/L ($p=0.04$) and of GGT of 10.7 U/L ($p=0.03$) was observed after 6 months of PPC therapy.⁴² Thus, the findings of these studies, along with our study results, point at a marked support to the liver function by EPL.

Dyslipidaemia is a well-established risk factor for NAFLD.⁶² In fact, patients with NAFLD usually have an atherogenic dyslipidaemia characterised by high levels of TG, LDL cholesterol and VLDL cholesterol, as well as a higher concentration of remnant lipoprotein cholesterol coupled with low HDL cholesterol levels.^{63 64} In this context, due to an increased cardiovascular risk, the treatment of dyslipidaemia should be considered in the management framework of NAFLD.⁶⁵ However, a recent retrospective study in 2566 patients with NAFLD found that the use of statins and other lipid-lowering agents did not have a positive effect on overall or cardiovascular mortality in NAFLD.⁶⁶ In our study, even though treatment with PPC in addition to statins and/or fibrates resulted in greater reductions in TG, TC, LDL and VLDL cholesterol levels and greater increases in HDL cholesterol compared with PPC only, the goal of TC<5.0 mmol/L was not achieved in one-third of patients on lipid-lowering therapy at 24 weeks of the study. This might be related to inadequate intensity and/or duration of statin therapy, and/or patient compliance with prescribed treatment. Nevertheless, this finding should be considered, as high blood cholesterol and impaired cholesterol metabolism may play a part in the development of cardiovascular disease in NAFLD.⁶⁶ It is also worth mentioning that in the present study, PPC-treated patients who did not undergo any form of lipid-lowering therapy had statistically significant improvements in lipid parameters throughout the 24-week study period, although to a lesser extent than patients treated with statins and/or fibrates. Although the observational nature of our study does not allow drawing conclusions on the efficacy of EPL in improving lipid parameters, we think that the effect of EPL supplementation on lipid profile is worthy of further investigation, considering that EPLs were found in non-clinical studies to have lipid-regulating effects.³⁴ This was also highlighted in several clinical studies. In 74 diabetic patients with NAFLD treated with either metformin alone or in combination with PPC for 3 months, Sun *et al* reported a significant decline in TC and TG levels in PPC-treated patients ($p<0.01$ compared with metformin monotherapy).⁴⁵ Similarly, in 185 diabetic patients with fatty liver who received basic drug therapy with or without PPC for 84 days, TG, TC and LDL cholesterol levels significantly decreased in the PPC group, and HDL cholesterol significantly increased (all $p<0.05$ compared with control).⁴⁴

Our study had certain limitations. First, this study, like all observational studies, was susceptible to information bias, and the lack of a comparator arm made it difficult

to assign a causal relationship to any possible treatment effect. Second, we used liver enzymes as a surrogate to assess the effectiveness of PPC administered as adjunctive therapy in patients with NAFLD. However, normal levels of liver enzymes have been detected in subjects with the entire histological spectrum of NAFLD.⁶⁷ Sanyal *et al* have suggested that novel cut-offs for liver enzymes are needed in order to prevent unnecessary diagnostic work-ups and to improve early detection of NAFLD.¹⁰ Third, liver biopsy was rarely performed in the present study to assess NAFLD. Although ultrasonography is a practical method with reasonable sensitivity and specificity, it may underestimate the actual rate of NAFLD, because ultrasonography changes appear at a hepatocyte fat content of 15% to 30%.^{49 68 69} Finally, although one of the most effective ways to reduce hepatic steatosis is weight loss, its effect could not be evaluated in our study population because most patients remained in the same weight range at the end of the study. Nevertheless, our study had several strengths, including its prospective and multicentric design; the large number of participants, which allowed us to identify the effect of PPC among stratified subgroup analyses; and the relatively long study duration. The inclusion of a large number of patients with comorbidities and from different cities reflects actual patient populations in daily clinical practice in Russia.

In conclusion, the results of our study suggest that PPC adjunctive therapy is effective in improving liver function markers of NAFLD in patients with associated metabolic comorbidities and that PPC might have a positive impact on serum lipid profile. The present study also indicates that liver transaminases can be useful markers for monitoring the progression of NAFLD over time. Importantly, a low rate of achieving lipid level targets was noted among patients treated with statins and/or fibrates, which might reflect potential patient non-compliance and inadequate dosing. Further data on the relation between liver transaminases and NAFLD might help to improve the diagnosis, management and risk prediction of NAFLD progression and to provide a more accurate indicator for chronic metabolic liver injury.
